Ground-state and finite-temperature properties of a special class of exactly solvable Ising-Heisenberg planar models are examined using the generalized decoration-iteration and star-triangle mapping transformations. The investigated spin systems exhibit an interesting quantum behaviour manifested in a remarkable geometric spin frustration, which appears notwithstanding the purely ferromagnetic interactions of the considered model systems. This kind of spin frustration originates from an easy-plane anisotropy in the XXZ Heisenberg interaction between nearest-neighbouring spins that favours ferromagnetic ordering of their transverse components, whereas their longitudinal components are aligned antiferomagnetically.

1 Introduction

Quantum behaviour of low-dimensional solids belongs to the most fascinating topics to be ever discovered in the field of condensed matter physics. Generally, it is expected that the clearest manifestations of quantum phenomena should emerge in the low-dimensional antiferromagnets which consist of spin carriers having low quantum spin number. With regard to this, much effort has recently been devoted to the two-dimensional antiferromagnetic spin systems that have an obvious relevance in elucidating the high-T_c superconductivity of cuprates [1], quantum phase transitions [2], geometric spin frustration [3], etc. On the other hand, the two-dimensional quantum ferromagnets remain rather unexplored from this point of view as their macroscopic quantum manifestations would be, on the contrary, rather surprising.

Nevertheless, the two-dimensional ferromagnetic spin systems with a spatial anisotropy represent very interesting systems as they may exhibit spontaneous long-range order possibly affected by quantum effects. A strong evidence supporting this statement has been provided by a recent exploration of outstanding quantum antiferromagnetic phase, which was discovered in the mixed-bond Ising-Heisenberg models (to be further abbreviated as IHMs) despite the pure ferromagnetic interactions of the considered model systems [4–6]. This remarkable finding suggests that an interesting quantum behaviour can also be found in the anisotropic ferromagnetic systems owing to a competition between the easy-plane XXZ Heisenberg interactions and the familiar Ising interactions of the easy-axis type. In the present article we shall show that this unusual behaviour represents a generic feature of wide class of the mixed-bond IHMs that arises independently of the lattice topology and hence, on close-packed lattices it leads to disordered ground state due to a presence of peculiar geometric spin frustration.

This paper is organized as follows. In the next section we shall briefly describe model systems and the method that enables to obtain their exact solution. The most interesting results are presented and discussed in Section 3. Finally, some concluding remarks are given in Section 4.

2 Model systems and their exact solution

Let us begin by considering periodic planar lattices composed of two kinds of spin sites; so-called Ising spins μ which interact with other spins through extremely anisotropic coupling $J_{\rm I}$ containing their one spatial component only and the Heisenberg spins S which interact among themselves via spatially anisotropic coupling $J(\Delta)$ containing all three spatial components. The parameter Δ allows to control a spatial anisotropy in the XXZ Heisenberg interaction, which can be either of easy-axis ($\Delta < 1$) or easy-plane ($\Delta > 1$) type. The total Hamiltonian of mixed-bond IHMs then includes both Ising as well as Heisenberg bonds and thus, it acquires this simple form

$$\hat{\mathcal{H}} = -J \sum_{(i,j)} [\Delta(\hat{S}_i^x \hat{S}_j^x + \hat{S}_i^y \hat{S}_j^y) + \hat{S}_i^z \hat{S}_j^z] - J_{\rm I} \sum_{(k,l)} \hat{S}_k^z \hat{\mu}_l^z, \tag{1}$$

where $\hat{S}_i^\alpha$ ($\alpha = x, y, z$) and $\hat{\mu}_j^z$ are spatial components of spin-1/2 operators, the first summation is carried out over the nearest-neighbouring Heisenberg spin pairs and the second summation runs over the nearest-neighbouring pairs of the Ising and Heisenberg spins, respectively.

In what follows we shall restrict ourselves to a special sub-class of the model Hamiltonian (1), namely, we will further refer just to spin systems that consists of Heisenberg spin pairs each interacting with either two or three nearest-neighbouring Ising spins. Several examples of such lattices are sketched in Fig. 1, where full (empty) circles denote lattice positions of the Ising (Heisenberg) spins. A common feature of the lattices a) and b) is that the Heisenberg spin pairs are placed in between two outer Ising spins (model A), while on lattices c) and d) they are surrounded by three outer Ising spins (model B). In view of further manipulations, it is very advisable to rewrite the total Hamiltonian as a sum of bond Hamiltonians, i.e. $\hat{\mathcal{H}} = \sum_k \hat{\mathcal{H}}_k$, each containing all the interaction terms of one Heisenberg pair (spin clusters on lhs of Fig. 2)

$$\hat{\mathcal{H}}_k = -J[\Delta(\hat{S}_{k1}^x \hat{S}_{k2}^x + \hat{S}_{k1}^y \hat{S}_{k2}^y) + \hat{S}_{k1}^z \hat{S}_{k2}^z\} - \hat{S}_k^z h_1 - \hat{S}_k^z h_2. \tag{2}$$

Above, $h_1 = h_2 = J_{\rm I}(\hat{\mu}_{k1}^z + \hat{\mu}_{k2}^z)$ for model A, while $h_1 = J_{\rm I}(\hat{\mu}_{k1}^z + \hat{\mu}_{k3}^z), h_2 = J_{\rm I}(\hat{\mu}_{k2}^z + \hat{\mu}_{k3}^z)$ for model B. On account of the commutability between different bond Hamiltonians, the partition function of IHMs can be partially factorized into a product of bond partition functions

$$\mathcal{Z}_{IHM} = \sum_{\{\mu\}} \prod_{k=1}^{N} \mathrm{Tr}_k \exp(-\beta \hat{\mathcal{H}}_k) = \sum_{\{\mu\}} \prod_{k=1}^{N} \mathcal{Z}_k, \tag{3}$$

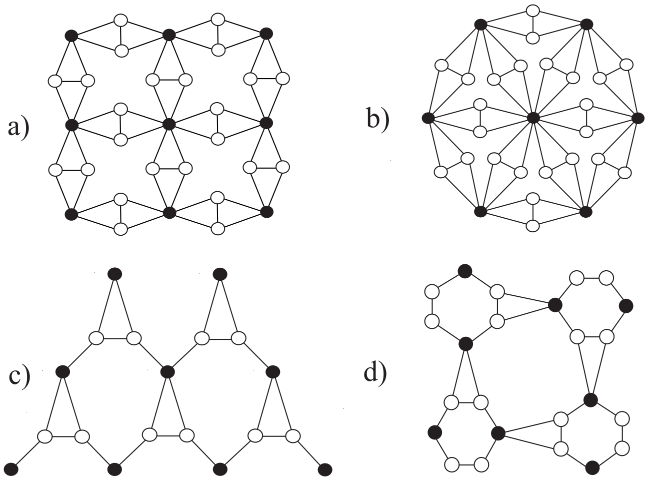

Fig. 1. Portions of several Ising-Heisenberg lattices. Full (empty) circles denote lattice positions of the Ising (Heisenberg) spins. Lattices a) and b) are further treated as a model A, lattices c) and d) as a model B.

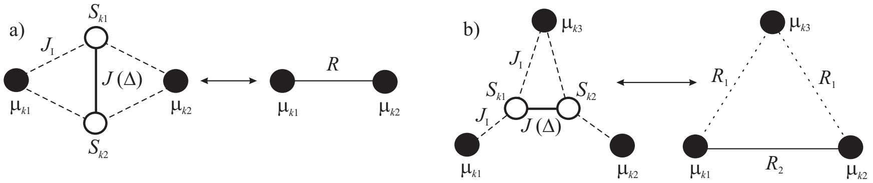

Fig. 2. Schematic representation of an extended: a) decoration-iteration and b) star-triangle transformation.

where $\beta = 1/(k_{\rm B}T)$, $k_{\rm B}$ is Boltzmann's constant, T denotes absolute temperature, the symbol Tr_k stands for a trace over spin degrees of freedom of kth Heisenberg spin pair and the summation $\sum_{\{\mu\}}$ runs over all available configurations of the Ising spins.

A crucial step of our approach represents calculation of the bond partition function $\mathcal{Z}_k$ accomplished by adopting the same steps as used in Ref. [4] and its subsequent replacement by suitable mapping transformation. For this purpose, we shall utilize generalized versions of the decoration-iteration [7] and star-triangle [8] transformations originally introduced by solving planar Ising models. It is noteworthy, however, that the mapping transformations have been later on remarkably generalized by Fisher [9,10] who firstly pointed out that *decorating* Ising spins may be, in principle, substituted by arbitrary statistical systems. In our case, both the transformations can be schematically illustrated as in Fig. 2 and mathematically they can be expressed as follows

$$\mathcal{Z}_k = 2\exp(\beta J/4)\cosh(\beta h_1) + 2\exp(-\beta J/4)\cosh(\beta J\Delta/2) = A\exp(\beta R\mu_{k1}^z\mu_{k2}^z), \quad (4)$$

$$\begin{aligned}\mathcal{Z}_k &= 2\exp(\beta J/4)\cosh[\beta(h_1+h_2)/2] + 2\exp(-\beta J/4)\cosh[\beta\sqrt{(h_1-h_2)^2+(J\Delta)^2}/2] \\ &= B\exp[\beta R_1(\mu_{k1}^z\mu_{k3}^z + \mu_{k2}^z\mu_{k3}^z) + \beta R_2\mu_{k1}^z\mu_{k2}^z], \end{aligned} \quad (5)$$

where A and R (B, R_1, and R_2) are unknown mapping parameters emerging in the decoration-iteration (star-triangle) transformation that are unambiguously given by a self-consistency condition of the mapping relations. Unknown mapping parameters can be calculated following the standard procedure [9, 10], for instance, the mapping (4) holds for model A if and only if

$$A = 2\exp(\beta J/4)(V_1 V_2)^{1/2}, \quad \beta R = 2\ln(V_1/V_2), \tag{6}$$

and the functions V_1 and V_2 are defined as follows

$$V_1 = \cosh(\beta J_{\mathrm{I}}) + \exp(-\beta J/2)\cosh(\beta J\Delta/2), \tag{7}$$
$$V_2 = 1 + \exp(-\beta J/2)\cosh(\beta J\Delta/2). \tag{8}$$

One the other hand, the model B can be treated within the mapping transformation (5) when

$$B = 2\exp(\beta J/4)(V_1 V_2 V_3^2)^{1/4}, \quad \beta R_1 = \ln(V_1/V_2), \quad \beta R_2 = \ln(V_1 V_2/V_3^2). \tag{9}$$

In addition to the functions V_1 and V_2 defined above we have introduced here another function

$$V_3 = \cosh(\beta J_{\mathrm{I}}/2) + \exp(-\beta J/2)\cosh\Big(\beta\sqrt{J_{\mathrm{I}}^2 + (J\Delta)^2}/2\Big). \tag{10}$$

At this stage, a direct substitution of the transformations (4) and (5) into the formula (3) gained for the partition function of IHMs leads to a mapping relationship with partition functions of the spin-1/2 Ising models on undecorated lattices (scheme from Fig. 2), in fact,

$$\text{Model A:} \qquad \mathcal{Z}_{IHM} = A^N \mathcal{Z}_{IM}(\beta, R), \tag{11}$$
$$\text{Model B:} \qquad \mathcal{Z}_{IHM} = B^N \mathcal{Z}_{IM}(\beta, R_1, R_2). \tag{12}$$

Notice that the mapping relations (11) and (12) allow simple calculation of other quantities as well. For easy reference, we list the most important ones: sub-lattice magnetization of the Ising spins $m_i^z \equiv \langle \hat{\mu}_{k1}^z \rangle$, sub-lattice magnetization of the Heisenberg spins $m_h^z \equiv \langle \hat{S}_{k1}^z \rangle$, pair correlation functions between the nearest-neighbouring Heisenberg spins $C_{hh}^{xx} \equiv \langle \hat{S}_{k1}^x \hat{S}_{k2}^x \rangle$, $C_{hh}^{zz} \equiv \langle \hat{S}_{k1}^z \hat{S}_{k2}^z \rangle$, and between the nearest-neighbouring Ising and Heisenberg spins $C_{ih}^{zz} \equiv \langle \hat{\mu}_{k1}^z \hat{S}_{k1}^z \rangle$.

3 Results and Discussion

In this section, the most interesting results for both investigated model systems will be presented and discussed in detail. Although the results obtained in the preceding section hold irrespectively of a character of the exchange parameters J and J_{I}, our further analysis will be for simplicity restricted to the ferromagnetic systems ($J > 0$, $J_{\mathrm{I}} > 0$) only. In order to avoid confusion, the results obtained for both investigated model systems will be discussed separately.

3.1 Model A

Initially, let us look more closely on the ground-state behaviour. The first-order transition line $\Delta_c = 1 + 2J_{\mathrm{I}}/J$ separates regions of stability of two different ground-state phases for both IHMs with a symmetric decoration shown in Fig. 1a)-b). As could be expected, there occurs a simple *ferromagnetic phase* (FP) characterized by saturated sub-lattice magnetization $m_i = 1/2$,

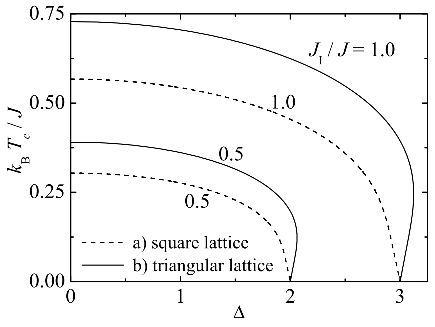

Fig. 3. Critical temperatures of IHMs with a symmetric decoration of the square (broken lines) and triangular (solid lines) lattices shown in Fig. 1a)-b).

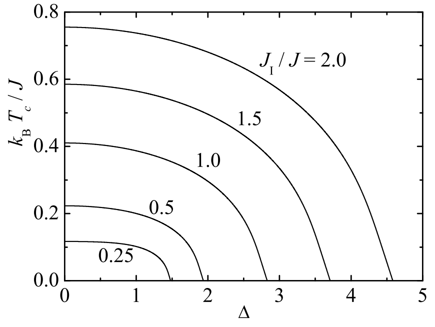

Fig. 4. Critical temperatures of IHMs with an asymmetric decoration of the triangular (Fig. 1c) and orthogonal-dimer (Fig. 1d) lattices.

$m_h = 1/2$, as well as pair correlation functions $C_{hh}^{zz} = 1/4$, $C_{ih}^{zz} = 1/4$ when the exchange anisotropy is below its critical value Δ_c. Within FP one also finds $C_{hh}^{xx} = 0$ clearly indicating classical character of this long-range ordered phase. However, there also appears a remarkable *disordered phase* (DP) without spontaneous ordering ($m_i = 0$, $m_h = 0$) when the exchange anisotropy exceeds its critical value Δ_c. It should be emphasized, nevertheless, that the Heisenberg spin pairs remain strongly correlated even within DP as suggested by $C_{hh}^{xx} = 1/4$ and $C_{hh}^{zz} = -1/4$. By contrast, the nearest-neighbouring Ising and Heisenberg spins are completely uncorrelated, indeed, one finds $C_{ih}^{zz} = 0$ within DP. Thus, it can be readily understood that DP emerges due to a peculiar geometric spin frustration originating from an antiferromagnetic alignment of the longitudinal components of the Heisenberg spins that accompanies preferred ferromagnetic ordering of their transverse components. In agreement with this statement, it can be easily checked that the function $|\Psi_{\rm DP}\rangle = \prod_i |\updownarrow\rangle_i \prod_k \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)_k$ describes the ground state of DP (the first product is carried out over all Ising spins and the second one runs over all Heisenberg spin pairs). According to this, one may conclude that all Ising spins are free to flip in DP on account of the spin frustration caused by Heisenberg spin pairs, which exhibit an interesting coexistence of ferromagnetic (transverse) and antiferromagnetic (longitudinal) correlations.

Now, let us step forward to the finite-temperature behaviour. The variation of critical temperature of IHMs with a symmetric decoration of the square (Fig. 1a) and triangular (Fig. 1b) lattices is displayed in Fig. 3 for two different values of $J_{\rm I}/J = 0.5$ and 1.0. As one can see, the critical lines of both the lattices terminate at common disorder point as predicted by the ground-state analysis. The most obvious difference in the criticality of both IHMs thus rests in a reentrant transition of the triangular lattice (Fig. 1b) observable in the vicinity of disorder points.

3.2 Model B

Ground-state behaviour of IHMs with an asymmetric decoration of the triangular (Fig. 1c) and orthogonal-dimer (Fig. 1d) lattices is strongly reminiscent to the one discussed earlier. As a matter of fact, the ground state constitute the aforementioned FP and DP that are bounded by the first-order transition line $\Delta_c = \sqrt{(1+3J_{\rm I}/J)(1+J_{\rm I}/J)}$. The occurrence of DP can be once again related to the spin frustration caused by the Heisenberg spins, which are antiferromagnetically aligned in the longitudinal direction and ferromagnetically coupled in the transverse direction. In the consequence of that, all Ising spins must be strongly frustrated because they interact with the longitudinal components of the Heisenberg spins only. Hence, one may conclude that an appearance of the disordered state $|\Psi_{\rm DP}\rangle = \prod_i |\updownarrow\rangle_i \prod_k \frac{1}{\sqrt{2}}(|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle)_k$ above certain Δ_c (depending on the lattice topology) represents a generic feature of all IHMs having the magnetic structure of some close-packed lattice.

Finally, we shall close our discussion with the finite-temperature phase diagram of IHMs with the asymmetric decoration of the triangular and orthogonal-dimer lattices. It is quite interesting to ascertain from Fig. 4 that the critical temperatures of both these lattices overlap as they exhibit almost the same decline (not discernible within the displayed scale) upon strengthening of Δ.

4 Conclusion

In the present article we have provided an exact solution to a special sub-class of IHMs which consist of the Heisenberg spin pairs coupled either to two or three outer Ising spins. The investigated spin systems exhibit an interesting quantum behaviour manifested in a remarkable kind of geometric spin frustration, which appears notwithstanding the purely ferromagnetic interactions of the considered model systems. We found a convincing evidence that this behaviour emerges due to a competition between the familiar Ising interactions and the easy-plane XXZ Heisenberg interactions, which favour ferromagnetic (antiferromagnetic) ordering of the transverse (longitudinal) components of the Heisenberg spin pairs. The most important question that arises from our study is whether this behaviour represents a general feature of all quantum models with mixed easy-axis and easy-plane bonds and whether it would persist also in the pure Heisenberg spin systems. This question represent a great challenge for our next investigations.
